We discuss the thermalisation process of the neutron stars crust described by solving the heat transport equation with a microscopic input for the specific heat of baryonic matter. The heat equation is solved with initial conditions specific to a rapid cooling of the core. To calculate the specific heat of inner crust baryonic matter, i.e., nuclear clusters and unbound neutrons, we use the quasiparticle spectrum provided by the Hartree-Fock-Bogoliubov approach at finite temperature. In this framework we analyse the dependence of the crust thermalisation on pairing properties and on cluster structure of inner crust matter. It is shown that the pairing correlations reduce the crust thermalisation time by a very large fraction. The calculations show also that the nuclear clusters have a non-negligible influence on the time evolution of the surface temperature of the neutron star.

## I. INTRODUCTION

The thermalisation process of the neutron stars crust can give important informations about the properties of the crust matter. This is indeed the case in the rapid cooling of isolated neutron stars [1] and in the thermal afterburst relaxation of neutron stars from X-ray transients [2]. In the rapid cooling process an important quantity is the cooling or thermalisation time of the crust, defined as the time needed for the crust matter to arrive to the temperature of the cold core. Since the outer crust and the envelope have high thermal conductivity, the cooling time is essentially determined by the inner crust matter, formed by nuclear clusters, unbound neutrons and ultrarelativistic electrons.

The thermalisation time of the crust depends essentially on the crust thickness [1]. However, several studies have shown that the thermalisation time depends also significantly on the superfluid properties of the inner crust baryonic matter [1, 3, 4, 5]. This dependence is induced through the specific heat of unbound neutrons, strongly affected by the pairing energy gap. Since the neutron pairing gap is influenced by the presence of the nuclear clusters [3, 6, 7], a reliable calculation of neutron specific heat should take the clusters into account. How the intensity of pairing correlations affects the specific heat of the neutrons in the presence of nuclear clusters was analysed in Ref. [8]. Thus, using the framework of Hartree-Fock-Bogoliubov (HFB) approach at finite temperature, it was shown that the specific heat can change with several orders of magnitude if the pairing gap is adjusted to describe two possible scenarios for neutron matter superfluidity, i.e., one corresponding to BCS approximation and the other to calculations schemes which take into account in-medium effects [9]. The impact which these changes in the specific heat could have on the ther-

malisation time was discussed in Ref. [4]. Employing a simple random walk model for the cooling [3, 10], in which the diffusion of the heat towards the core was calculated without taking into account the dynamical change of the temperature through the whole crust, it was shown that the thermalisation times corresponding to the two pairing scenarios mentioned above differs by a large fraction, which could be easily discriminated observationally. The scope of this paper is to present more accurate estimations of the thermalisation time obtained by employing a more realistic cooling model based on dynamical solutions of the heat equations and on a state-of-the-art description of the specific heat for baryonic matter.

## II. THE MODEL OF CRUST THERMALISATION

The crust thermalisation is described here in the rapid cooling scenario in which the core arrives quickly to a much smaller temperature than the crust. Due to this temperature inversion the heat stored in the crust diffuses into the core where it is dissipated by the neutrinos. The heat diffusion through the crust can be described by the relativistic heat equation [11]:

$$\frac{\partial}{\partial r} \left[ \frac{Kr^2}{\Gamma(r)} e^\phi \frac{\partial}{\partial r} (e^\phi T) \right] = r^2 \Gamma(r) e^\phi \left( C_V \frac{\partial T}{\partial t} + e^\phi Q_\nu \right), \quad (1)$$

where  $T$  is the temperature,  $t$  is the time,  $K$  is the thermal conductivity,  $C_V$  is the specific heat and  $Q_\nu$  is the neutrino emissivity. The effect of the gravity is given through the gravitational potential  $\phi$ , which enters in the definition of the redshifted temperature  $\tilde{T} = Te^\phi$ , and the quantity  $\Gamma(r) = (1 - 2Gm(r)/rc^2)^{-1/2}$ , where  $G$  is the gravitational constant and  $m(r)$  is the gravitational mass included in a sphere of radius  $r$ . The latter is obtained solving the Tolman-Oppenheimer-Volkoff equation.

In principle, the radial mass distribution and the properties of the inner crust employed in the heat equation

---

\*corresponding author (email:sandulescu@theory.nipne.ro)

should be determined consistently from the same equation of state (EOS) of nuclear matter. To describe in an unified way both the crust and the core here we use the EOS given by the Skyrme interaction SLy4 [12], which provides a reasonable star model [13] for the present study. The cooling calculations are done for a neutron star with a mass equal to  $1.44 M_\odot$ . For this mass it is predicted a total star radius of 11.59 km and a central density of  $3.51 \rho_0$ , where  $\rho_0 = 2.9 \times 10^{14} \text{ g.cm}^{-3}$  is the saturation density for symmetric nuclear matter. The inner crust, defined here as the part of the star with the density ranging between  $\rho_0/2$  and  $\rho_{drip} = 3.285 \times 10^{11} \text{ g.cm}^{-3}$ , extends from  $R_c = 10.74 \text{ km}$ , which is the radius at the core-crust interface, to 11.29 km.

The heat equation (1) is solved in the region of the inner crust matter. Since during the fast thermalisation the energy loss due to the neutrino emission in the crust is negligible we take  $Q_\nu = 0$ . The initial temperature distribution in the crust and the boundary condition at the core-crust interface are chosen to simulate a rapid cooling process. Thus, at  $t = 0$  it is supposed that the crust has a flat temperature, i.e.,  $\tilde{T}(r, t = 0) = T_i$ . We also consider that at the outer border of the crust the gradient of the temperature vanishes.

The temperature evolution at the core-crust interface is obtained from Eq.(1) supposing that the radial distribution of the core temperature is uniform,  $\partial \tilde{T} / \partial r = 0$ . From Eq. (1) one thus gets

$$\frac{\partial T(r = R_c, t)}{\partial t} = -\frac{e^{\phi(R_c)} Q_\nu}{C_V} \quad (2)$$

Considering that the neutrino emissivity in the core is given by  $Q_\nu = Q_f T_9^6$  [14], where  $T_9 = T/10^9 \text{ K}$ , and supposing that during the crust thermalisation the specific heat remains constant in time we finally obtain

$$T(r = R_c, t) = T_i (1 + \epsilon T_i^5 t)^{-1/5} \quad \text{with } \epsilon = \frac{5e^{\phi(R_c)} Q_f}{C_V}. \quad (3)$$

For the constant  $Q_f$ , characterizing the fast neutrino emission in the core matter, we have taken the value  $Q_f = 10^{26} \text{ erg.cm}^{-3} \text{ s}^{-1}$  [14].

The physical quantities which are essential for the crust thermalisation are the thermal conductivity and the specific heat. In the inner crust the thermal conductivity is primarily determined by the electrons. Here we use the thermal conductivity parametrized by Lattimer et al[1] starting from the calculations of Itoh et al [15]. For temperatures above  $10^8 \text{ K}$ , as used in this paper, the conductivity is nearly independent of the temperature and is given by  $K = C(\rho/\rho_0)^{2/3}$ , where  $C = 10^{21} \text{ ergs cm}^{-1} \text{ s}^{-1}$  and  $\rho$  is the baryonic density.

### III. SPECIFIC HEAT OF THE INNER CRUST MATTER

The specific heat of the inner crust has contributions from the electrons, the lattice and the unbound neutrons.

They are calculated for a given set of densities in the Wigner-Seitz approach. Since the electrons are ultrarelativistic, they are considered as an uniform degenerate gas with the specific heat given by [16]:

$$C_V^{(e)} = \frac{k_B (3\pi)^{2/3}}{3\hbar c} \left( \frac{Z}{V} \right)^{2/3} T, \quad (4)$$

where  $V$  is the volume of the Wigner-Seitz cell and  $Z$  is the number of the electrons in the cell (which is equal with the number of protons).

For the specific heat of the lattice we use the approximation employed in Ref.[17], i.e.,  $C_V^{lattice} = 3k_B/V$ , where, as above,  $V$  is the volume of the cell and  $k_B$  is the Boltzman constant.

We shall now discuss the temperature dependence of the specific heat of neutrons, which requires more elaborate calculations. The specific heat is calculated from the quasiparticle energies obtained solving the HFB equations at finite-temperature in the Wigner-Seitz approximation. The details of the HFB calculations in a Wigner-Seitz cell are given in Ref. [8]. In the HFB calculations the mean field is described with the same interaction used in the star model, i.e., the Skyrme force SLy4. A completely consistent cooling simulation would require a inner crust with a Wigner-Seitz cells structure calculated from the same interaction. Since at present such cells structure is not available, here we shall use the Wigner-Seitz cells determined in Ref.[18]. Their properties are summarize in Table I (see the Appendix).

The pairing correlations in the inner crust matter are described with a density dependent contact force of the following form [19]:

$$V(\mathbf{r} - \mathbf{r}') = V_0 [1 - \eta (\frac{\rho(r)}{\rho_0})^\alpha] \delta(\mathbf{r} - \mathbf{r}'), \quad (5)$$

where  $\rho(r)$  is the baryonic density. To analyse the dependence of the crust thermalisation on the intensity of pairing correlations, in the calculations we have used two sets of parameters for the pairing force. They are chosen to simulate two possible scenarios for pairing in neutron matter corresponding to : (1) BCS calculations with realistic two-body interactions extracted from nucleon-nucleon scattering [9]; in this approximation the maximum pairing gap in uniform neutron matter is about 3 MeV; (2) calculations which go beyond the BCS approximation by taking into account in-medium effects on two-body interaction and self-energy; here we shall consider those calculations which predicts a maximum pairing gap in neutron matter of about 1 MeV [20, 21]. These two scenarios, called below strong and weak pairing, can be simulated by using two pairing forces with the same parameters for the density dependent part, namely  $\eta = 0.7$  and  $\alpha = 0.45$ , and two different strengths, i.e.,  $V_0 = \{-570, -430\} \text{ MeV fm}^{-3}$ . These parameters have been used with an energy cut-off in the quasiparticle spectrum, required by the zero range of the pairing force.

FIG. 1: Neutron-specific heats in various Wigner-Seitz cells for strong pairing. The specific heat is given in units of Boltzmann constant  $k_B$ .

The cut-off was introduced smoothly, i.e., by an exponential factor  $e^{-E_i^2/100}$  acting for  $E_i > 20$  MeV, where  $E_i$  are the HFB quasiparticle energies.

With the setting discussed above we have solved the HFB equations for a given Wigner-Seitz cell and determined the quasiparticle spectrum  $E_i$  and the corresponding entropy, i.e.,

$$S = -k_B \sum_i (2j_i + 1) (f_i \ln f_i + (1 - f_i) \ln(1 - f_i)). \quad (6)$$

where  $f_i = [1 + \exp(E_i/k_B T)]^{-1}$  is the Fermi distribution and  $T$  is the temperature. From the entropy we then calculated the specific heat of the neutrons

$$C_V = \frac{T}{V} \frac{\partial S}{\partial T}, \quad (7)$$

where  $V$  is the volume of the Wigner-Seitz cell.

The specific heat was calculated for all temperatures needed in the thermalisation process. Here we show the

FIG. 2: Neutron-specific heats in various Wigner-Seitz cells for weak pairing. The specific heat is given in units of Boltzmann constant  $k_B$ .

results for temperatures up to 500 keV. How looks the temperature dependence of specific heat for the two scenarios of the pairing intensity is shown in Figs.(1,2). As noticed already in Ref.[8], we can see that the specific heat has very different values for the two pairing scenarios. It is also interesting to notice that the specific heats of the cells have rather different temperature dependence. Thus, for the strong pairing scenario, shown in Fig. 1, the specific heat is in the superfluid regime for the first 5 cells (upper panel). This is not the case for the next cells (bottom pannel) where in the same temperature range there is a transition from the superfluid to the normal phase, as clearly seen for the cells nr. 6-8 (for the last two cells the transition temperature cannot be noticed because is too small). On the other hand, as seen in Fig. 2, for the weak pairing the specific heat is entirely in the superfluid regime only for the first two cells.

To illustrate the particular behavior of the specific heat in non uniform matter and the validity of various approximations, in what follows we shall discuss in more detail

FIG. 3: Neutron-specific heat in the the Wigner-Seitz cell nr 6 for strong pairing. The results corresponds to various approximations discussed in the paper. The specific heat is given in units of Boltzman constant  $k_B$ .

the results for the cell nr. 6, which contains  $N=460$  neutrons and  $Z=40$  protons (see Appendix A). In this cell the HFB calculations predict 378 unbound neutrons. It is interesting that in spite of many neutrons in the cell the number of the bound neutrons in the cluster with  $Z=40$  protons is equal to the magic number 82, as for the dripline nucleus  $^{122}\text{Zr}$  (see, e.g., Ref.[22]). The specific heat given by the HFB spectrum, in which the contribution of the cluster is included, is shown in Fig.3 by full line. In the same figure are shown also the specific heats corresponding to two approximations employed in some studies [1, 3]. In these approximations the non uniform distribution of the neutrons is replaced with a uniform gas formed by the total number of neutrons in the cell or by taking only the number of the unbound neutrons. The latter case is considered as an effective way of taking into account the influence of the cluster [3]. How these approximations work is seen in Fig.3. To make the comparison meaningful, the calculations for the uniform neutron gas are done solving the HFB equations with the same boundary conditions as for the non uniform system, i.e., neutrons+cluster. As seen in Fig.3, the transition from the superfluid to the normal phase is taking place at a lower temperature in the case of uniform neutron gas, especially when are considered only the unbound neutrons. We can also notice that, in contrast to the uniform system, in the non uniform system the transition from the superfluid to the normal phase is smooth.

To see better what happens in a non uniform system, in Fig.4 is shown the evolution with the temperature of the pairing field in the cell nr. 6. We can notice that at zero temperature the pairing field is much larger in the surface of the cluster than in the bulk region. Due to this fact by increasing the temperature the pairs corresponding to the neutrons localized preferentially in the surface

FIG. 4: Radial distribution of the pairing field for the Wigner-Seitz cell nr. 6 for various temperatures. The results correspond to a strong pairing.

FIG. 5: Neutron-specific heat in the Wigner-Seitz cell nr. 6 for strong pairing. Here the results are shown up to high temperatures in order to illustrate the second transition region around  $T=900$  keV. The specific heat is given in units of  $k_B$ .

region of the cluster are destroyed gradually and much slower compared to the pairs formed by neutrons localized far from the surface of the cluster. In fact, as shown in Fig.5, the non uniform system shows two transition regions, one around  $T=200$  keV, corresponding mainly to the neutrons located far from the surface of the cluster, and another one, much less pronounced, around  $T=900$  keV, which corresponds to the neutrons localised in the surface region of the cluster.

#### IV. CRUST THERMALISATION

In this section we discuss the crust thermalisation obtained by solving the heat equation (1) with the specific heats presented in the previous section. The time evolution of the temperature in the inner crust is illustrated in Fig.6 which shows the results obtained for an initial temperature  $T_i=500$  keV. One can see that the crust thermalisation is strongly enhanced by the presence of pairing correlations.

Of physical interest is the time evolution of the so-called apparent surface temperature seen by a distant observer,  $T_{inf}$ . For a non-magnetized envelope composed by iron and light element the surface temperature  $T_{inf}$  is given by [23]

$$T_{inf} = T_{eff} \sqrt{1 - \frac{2GM}{c^2 R}} \quad (8)$$

where

$$\begin{aligned} T_{eff} &= 10^6 \left[ \frac{g}{10^{14}} \left( (7\zeta)^{2.25} + (\zeta/3)^{1.25} \right) \right]^{(1/4)} \\ \zeta &= T_{b9} - (T_*/10^3) \\ g &= GM/R \sqrt{1 - GM/c^2 R} \end{aligned}$$

In the equations above  $T_* = (7T_{b9}\sqrt{g_{14}})^{1/2}$  where  $g_{14} = g/10^{14}$ ,  $T_{b9} = T_b/10^9$  and  $T_b$  is the temperature at the outer edge of the inner crust provided by the heat equation.

The time evolution of the surface temperature  $T_{inf}$  is displayed in Fig.7 for three initial temperatures of the crust,  $T_i = \{100, 300, 500\}$  keV. We can clearly notice that the pairing is reducing significantly the thermalisation time of the crust. For example, as seen in Fig.7, bottom panel, the cooling time drops from about 75 years, the value obtained when the neutrons are considered in the normal phase, to about 55 years for weak pairing and to about 30 years for strong pairing. Thus the two

FIG. 7: Time evolution of the surface temperature for the initial temperatures  $T_i = \{100, 300, 500\}$  keV.

pairing scenarios give very different predictions for the thermalisation time. The same conclusion was obtained previously in a schematic cooling model [4]. However, the latter predicts very different thermalisation times compared to the realistic cooling model employed here.

In Fig.7 are shown also the thermalisation times obtained by neglecting the effect of the clusters, i.e., supposing that the baryonic matter in the inner crust is uniform. In this case the specific heat of the neutrons is calculated from the quasiparticle spectrum of BCS equations solved for infinite matter. For the BCS calculations we have used the single-particle energies provided by the asymmetric nuclear matter with the same neutron to pro-

ton fraction as in the Wigner-Seitz cells of Table I. As seen in Fig.7, the results for the weak pairing scenario indicate that the surface temperature is dropping faster for uniform matter than for non uniform matter. For the strong pairing the behaviour is opposite. Thus the clusters have a non-negligible and a non-trivial effect on the time evolution of the surface temperature.

In order to test the effect of the protons on uniform matter calculations we have also evaluated the time evolution of the surface temperature considering only a uniform gas of neutrons, i.e., neglecting in the BCS equations the contribution of the protons to the single-particle energies of neutrons. The results are very similar to the ones obtained for the uniform asymmetric matter.

## V. SUMMARY AND CONCLUSIONS

In this paper we have studied how the thermalisation of neutron stars crust depends on pairing properties and the cluster structure of the inner crust matter. The thermal evolution was obtained by solving the relativistic heat equation with initial conditions specific to a rapid cooling process and supposing that during the thermalisation there are no sinks or sources of energy in the crust. The specific heat of neutrons was calculated from the HFB spectrum, taking into account consistently the effects of nuclear clusters, pairing correlations and temperature. The thermal evolution of the inner crust was analysed using for the neutrons two sets of specific heats obtained with a strong and a weak pairing force which simulate two possible scenarios for the intensity of pairing correlations in neutron matter. The results show that the crust thermalisation is strongly influenced by the intensity of pairing correlation. This result confirm what it was found earlier in Ref. [4] with a schematic cooling model. However, the latter predicts thermalisation times which are very different from the results obtained with the realistic cooling model employed in this study. We have also

shown that the cluster structure of the inner crust affects significantly and in a non-trivial way the time evolution of the surface temperature, mainly for weak pairing and before the thermal equilibrium between the crust and the core is reached.

**Acknowledgment.** We thank P. M. Pizzochero for valuable discussions and for his help in solving the heat equation. This work was supported by ESF through the project "The New Physics of Compact Stars" and by CNCSIS through the grant IDEI no. 270.

## VI. APPENDIX A

In this appendix are summarized the properties of the Wigner-Seitz cells determined in Ref. [18] and used in this paper. Compared to Ref. [18], here we didn't include the most dense cell, which is close to the region of more complicated pasta phases.

| cell | N    | Z  | $R_{WS}$<br>[fm] | $\rho$<br>[g.cm <sup>-3</sup> ] |
|------|------|----|------------------|---------------------------------|
| 10   | 140  | 40 | 54               | $4.7 \times 10^{11}$            |
| 9    | 160  | 40 | 49               | $6.7 \times 10^{11}$            |
| 8    | 210  | 40 | 46               | $1.0 \times 10^{12}$            |
| 7    | 280  | 40 | 44               | $1.5 \times 10^{12}$            |
| 6    | 460  | 40 | 42               | $2.7 \times 10^{12}$            |
| 5    | 900  | 50 | 39               | $6.2 \times 10^{12}$            |
| 4    | 1050 | 50 | 36               | $9.7 \times 10^{12}$            |
| 3    | 1300 | 50 | 33               | $1.5 \times 10^{13}$            |
| 2    | 1750 | 50 | 28               | $3.3 \times 10^{13}$            |
| 1    | 1460 | 40 | 20               | $7.8 \times 10^{13}$            |
